Preparation

Installation of required packages

```
# install.packages('dplyr')
library(dplyr)
```

General overview

Packages to consider:

- apply function family to apply function to vectors in a more efficient way than loops.
- dplyr package for human readable and efficient data managment.
- **vroom** package for fast reading of delimited datasets (e.g. large csv files). See e.g. vignette("vroom") for a description.
- data.table package to work with large datasets and have a similar syntax as base R.

apply

Generally: apply a function to an object. This is generally faster than looping over data.

- apply: the base function apply(x, MARGIN, FUN) applies functions to matrices
 - x is the object
 - MARGIN is the dimension to which is should be applied (1 represents rows, 2 represents columns)
 - FUN is the function that should be applied to the object
- lapply: applies a function to a list (or vector and data.frames) and returns a list
- **sapply**: works like lapply, but tries to *simplify* the results (can also be achieved most of the time with "unlist(lapply(...))").
- Others:
 - **mapply**: from *multivariate* apply
 - tapply: apply a function to categories defined by a factor variable.
 - rapply: recursively applies a function to a list.
 - **vapply**: allows the specification of the return format.

Application: calculate means for wordcount and the page number of articles by section

Load our sample data with about 21,000 Guardian articles:

```
load("data/guardianapi_uknews_combined.Rda")

And already split the articles by section:
garticles_split <- split(garticles, garticles$sectionId)
class(garticles_split) # a list of data.frames. For each section a separate data.frame

[1] "list"
head(names(garticles_split)) # The names of the list items. Each is the name of the sections

[1] "uk-news" "travel" "business" "environment" "politics"
[6] "culture"</pre>
```

Generate the statistics using a for loop

```
mean_wordcount mean_pagenumber
                   825.419
                                   13.16170 1661
uk-news
                                   13.24823 272
travel
                  1221.165
                  1067.757
                                   29.98241 2106
business
environment
                   715.019
                                   16.18851 843
politics
                  1370.844
                                   10.58297 2404
culture
                  1309.587
                                   14.86331 184
  user system elapsed
  0.042
         0.001
                  0.044
```

Generate the statistics using the apply family

```
mean_wordcount mean_pagenumber
                   825.419
                                  13.16170 1661
uk-news
travel
                  1221.165
                                  13.24823 272
business
                  1067.757
                                  29.98241 2106
environment
                   715.019
                                  16.18851 843
politics
                  1370.844
                                  10.58297 2404
                  1309.587
                                  14.86331 184
culture
  user system elapsed
  0.023
         0.000
                  0.024
```

dplyr

Data manipulation grammar for R. Its very user friendly and connects to many innovative developments in R.

- very fast in comparison to base R
- uses verbose language that makes code human readable (contrast to e.g. data.table)

Base functions

- filter() to select cases based on their values. Extracts rows that meet logical criteria.
- arrange() to reorder the cases. Orders rows by values of a column.
- select() to select variables based on their names. rename() to rename the columns of a data frame.
- mutate() and transmute() to add new variables that are functions of existing variables. Mutate keeps old variables, transmute removes the original rows.
- summarise() to summarise data into single row of values. This is a new data frame then and not an appended column.
- sample_n() and sample_frac() to take random samples.

More information and an overview: https://rstudio.com/wp-content/uploads/2015/02/data-wrangling-cheatsheet.pdf

```
rm(list = ls())
load("data/guardianapi_uknews_combined.Rda")
```

Example: filter()

Extract rows that meet logical criteria.

```
# Base R
system.time({
   extracted <- garticles sectionId == "business" & garticles wordcount >
       700, ]
})
  user system elapsed
 0.002
         0.001
                 0.002
# dplyr
system.time({
   extracted <- dplyr::filter(garticles, sectionId == "business", wordcount > 700)
})
  user system elapsed
 0.005
        0.001
                 0.006
```

Example: mutate()

Add new variables that are functions of existing variables.

```
# Base R
system.time({
    garticles$about_economics <- garticles$sectionId %in% c("money", "business")</pre>
})
   user system elapsed
      0
              0
# dplyr
system.time({
    garticles <- dplyr::mutate(garticles, about_economics = sectionId %in% c("money",</pre>
        "business"))
})
   user system elapsed
  0.005
         0.000
                  0.005
```

Example: group by()

groupy_by() allows the splitting of a dataset into subgroups and which can then be used to be processed further.

Here we calculate the same summary statistics as before with base R and the apply function: we calculate the average wordcount and page number for each section.

```
# dplyr
system.time({
    by_section <- dplyr::group_by(garticles, sectionId)</pre>
```

	sectionId	${\tt wordcount}$	${\tt pageNumber}$	${\tt count}$
	<fct></fct>	<dbl></dbl>	<dbl></dbl>	<int></int>
1	uk-news	825.	13.2	1661
2	travel	1221.	13.2	272
3	business	1068.	30.0	2106
4	${\tt environment}$	715.	16.2	843
5	politics	1371.	10.6	2404
6	culture	1310.	14.9	184
7	us-news	1021.	13.1	265
8	money	741.	35.9	393
9	film	990.	17.0	529
10	world	957.	16.1	1672
#	with 57 m	nore rows		

The time to process is about 4-5 times faster than either solutions from base R!

As you can see, the result is returned as a tibble. Tibbles are comparable to data frames in their behavior.

- In a sense, it does less than a data.frame as it removes redundant features, such as automatically converting variables or introducing row.names.
- tibbles habe better properties when inspecting e.g. the head of a dataset, as it will not print as many lines as a data.frame.
- tibbles are more restrictive than data.frames. As such, tibbles will throw an error if you try to access a variable that doesn't exist in the dataset, while data.frames will match names.

You can find more information by typing vignette("tibble") if interested.

The pipe operator %>%

dplyr (and other packages of the tidyverse) make use of a pipe operator %>%. Instead of saving results in intermediate data.frames or replacing the current data.frame in every line, we can transfer the output of one operation directly to the next. This saves space and makes the code more readable (because we need to use less parentheses).

A tibble: 67×4

```
sectionId
              wordcount pageNumber count
  <fct>
                  <dbl>
                              <dbl> <int>
                               13.2 1661
1 uk-news
                   825.
2 travel
                  1221.
                               13.2
                                      272
                  1068.
                               30.0 2106
3 business
                               16.2
4 environment
                   715.
                                      843
5 politics
                  1371.
                               10.6 2404
```

```
6 culture
                     1310.
                                  14.9
                                          184
 7 us-news
                                          265
                     1021.
                                  13.1
8 money
                      741.
                                  35.9
                                          393
9 film
                      990.
                                  17.0
                                         529
10 world
                      957.
                                  16.1
                                        1672
# ... with 57 more rows
```

Can be rewritten to:

```
res <- garticles %>%
    group by(sectionId) %>%
    summarise(wordcount = mean(wordcount, na.rm = T), pageNumber = mean(newspaperPageNumber,
        na.rm = TRUE), count = n()
res
```

A tibble: 67 x 4

	sectionId	wordcount	${\tt pageNumber}$	count
	<fct></fct>	<dbl></dbl>	<dbl></dbl>	<int></int>
1	uk-news	825.	13.2	1661
2	travel	1221.	13.2	272
3	business	1068.	30.0	2106
4	${\tt environment}$	715.	16.2	843

#	with 57 r	nore rous		

... with 57 more rows

data.table

data.table is a format that allows the storage and handling of large datasets. It is comparable to the data processing with dplyr. data.table seems to perform better for really large datasets and is more similar to the syntax of data frames of base R. So if you are already familiar with the data frame notation you might prefer this syntax.

Repetion data.frames:

- You can access the variables (columns) of a data.frame in two ways:
 - df\$variable selects the column 'variable'
 - df[,c("variable")] selects the column 'variable' as well. This is more useful if you want to select multiple columns
- You subset data frames by referring to conditions on their rows and columns. Everything that is before the "," refers to rows. Everything that's after the "," refers to the columns. Above we introduced the condition dfscolumn == "variable".
 - df[df\$variable == 1,] conditions on the rows. This would lead to a subsetting of the data.frame in a sense that we only get rows where a particular 'variable' has the value 1.

data.table

Now, data table allows for the same syntax, but follows a logic that is similar to SQL (language which is used in data bases). The additional processes are appended after the regular syntax leading to the general formulation:

• data.table[subsetting, operation, grouping]

- subsetting: This is what happens before the first comma. This is similar to the data frame.
 - * data.table[variable1 == 'A'] selects only rows where the column 'variable1' is equal to 'A'.
- operations: This is what happens after the first comma and before the second comma. This is an enhanced conditioning on the columns as they not only allow for the subsetting of the columns, but also for their modification.
 - * data.table[, .(variable1, variable2)] selects every row but only the two columns 'variable1' and 'variable2'. The .(...) represents an operation: select only two variables.
 - * data.table[variable1 == "A", .(variable1, variable2)] selects only rows where the column 'variable1' is queal to 'A' (subsetting) and then displays only the two columns 'variable1' and 'variable2' (operation). If you like to, you could also use the old syntax: data.table[data.table\$variable1 == "A", c("variable1","variable")]
 - * data.table[variable1 == "A", .(sum = variable1 + variable2)] selects rows where the column 'variable1' is equal to 1 (subsetting) and then calculates a sum for those observations for the columns 'variable1' and 'variable2' (operation) and reports it as 'sum'.
 - * Note: . N can be used as an operation to calculate the number of observations.
- **grouping**: Aggregations can be done in the third part of the syntax. E.g. apply an operation to each subgroup of the dataset.
 - * data.table[variable1 == 'A', .N, by = variable2] Calculates the number of observations (operation: .N) for each group existent in column 'variable2' and but only for observations where the column 'variable1' has the value 'A'.

```
rm(list = ls())
library(data.table)
load("data/guardianapi_uknews_combined.Rda")
gadt <- data.table::as.data.table(garticles)</pre>
```

Suppose we would like to receive the same summary statistics (mean wordcount, mean page number) as in the above exercises. Using data.table commands, we would write it as follows:

```
sectionId mean_wordcount mean_pagenumber count
1:
       uk-news
                       825.419
                                       13.16170
                                                 1661
2:
        travel
                      1221.165
                                       13.24823
                                                  272
3:
      business
                      1067.757
                                       29.98241
                                                 2106
4: environment
                       715.019
                                       16.18851
                                                  843
5:
      politics
                      1370.844
                                       10.58297
                                                 2404
6:
       culture
                      1309.587
                                       14.86331
                                                  184
   user system elapsed
  0.017
          0.001
                  0.008
```

Generating these statistics with data table is even almost a factor 2 faster than the dplyr solution!
